13. ABSTRACT *(Maximum 200 words)*

Minimum visible lesion (MVL) threshold measurements at the retina for rhesus monkey eyes are reported for femtosecond, picosecond, and nanosecond single laser pulses using visible wavelengths. Estimates of the dose causing 50% probability for damage (ED_{50}) are calculated for 1-hour and 24-hours postexposure as well as the 95% fiducial intervals for ED_{50}. The ED_{50} values are found to be dependent on both wavelength and pulsewidth, and for a single wavelength are, in general, lower for short pulsewidths, with the exception of values at the shortest pulsewidth of 90 fs at 580 nm. At 90 fs the ED_{50} dosages were noted to increase slightly when compared with the 3-ps and 600-fs values, all three delivered at 580-nm wavelength. The 4-ns ED_{50} value was more than double the value at 60 ps delivered at 532-nm wavelength. Fluorescein angiography was accomplished at 1-hour and 24-hours postexposure and did not demonstrate lower threshold for damage, which has been the case for MVLs created with longer pulse duration (greater than 1 ns) or for rabbit eyes at the same pulsewidths as measured in our laboratory.

INTRODUCTION

The National Laser Safety Standard, ANSI Z136.1-1993[1], defines a maximum permissible exposure (MPE) for the retina from visible and near-infrared laser radiation. This standard applies to pulse durations down to 1 nanosecond (ns); it is based on retinal injury studies conducted on primate eyes for continuous-wave and pulsed laser systems with pulsewidths greater than 2 ns. The few retinal studies that have been reported for pulsewidths less than 1 ns in the rhesus monkey eyes[2-6] were almost all for picosecond (ps) pulsewidths. Two studies have been reported for femtosecond (fs) pulses in rabbits. In one study, Birngruber et al.[7] measured the 50% probability for damage (ED_{50}) visible threshold dosage in chinchilla gray rabbit eyes for 80-fs pulsewidths at 625 nanometers (nm). In the other study, Toth et al.[8] reported damage thresholds for 90-fs pulsewidths at 580 nm in the dutch-belted rabbit.

This study utilizes rhesus monkey[9] eyes to determine the ED_{50} threshold doses necessary to create visible lesions in the macular region for various pulsewidths from 4 ns down to 90 fs. Our goal in this study was to evaluate retinal damage thresholds for single pulsewidths in the rhesus monkey fundus. Further, our goal was to acquire urgently needed data to assess potential human retinal hazards that could be applied to new national laser safety standards for subnanosecond laser systems operating in the visible and near-infrared spectral regions. We have determined the threshold dosages for visible lesions for pulsewidths of 90 and 600 fs and 3 ps at 580 nm and for pulsewidths of 60 ps and 4 ns at 532 nm. These subnanosecond laser ocular tissue interaction studies are critical in identifying hazards to the human eye and in considering future clinical applications in laser surgery. Such studies also provide new insight into the biological information of intense electromagnetic fields. In our work, we define a "visible lesion" as a visible change in the fundus readily seen by at least two observers. Both observers must agree that the change in the fundus is actually a lesion before that exposure site is counted as a positive event. A minimum visible lesion (MVL) then is defined as a change in the fundus due to laser insult just minimally visible by the two observers, either ophthalmoscopically or from photographs of fluorescein angiography (FA).

In an earlier study we had determined the ED_{50} MVL dosages for dutch-belted rabbit eyes[8,10,11] from 5 ns down to 90 fs; herein we present our findings for the rhesus monkey eyes.[6] For the present primate study we found a notably lower threshold for MVLs compared with our rabbit studies. These results are important in providing eye safety information because laser systems capable of producing subnanosecond pulses are in widespread use throughout the research, medical, and military communities. The low energy required for intraretinal hemorrhages was identified although subretinal hemorrhages were similarly difficult to create (or more so than in the rabbit). These studies demonstrate that the rabbit model cannot be extrapolated to predict human ocular injury.

METHODS

Experimental Systems

The ultrashort pulse laser system shown in Figure 1 produces a range of pulsewidths, wavelengths, and energy levels with relative ease of reconfiguration. It produces single pulses with an adjustable pulse repetition rate between single pulses and 10 pulses per second (pps). All pulses generated can have energies greater than 100 microjoules (μJ). This system consists of a dye laser pumped by a mode-locked (82 megahertz (MHz)), pulse-compressed, frequency-doubled neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. The dye laser output is amplified by a three-stage pulse dye amplifier (PDA) which is pumped by a seeded, frequency-doubled Nd:YAG regenerative amplifier. Pulsewidths are measured by an INRAD Slow Scan Autocorrelator. The pulses from the PDA can also be compressed to achieve below 100-fs pulses by chirping the pulses before amplifying and rephasing the spectrally broadened pulse in time thereby giving rise to the compressed pulse afterwards. The PDA pulsewidths range between 3 ps and 90 fs at 580 nm. Pulses of 60 ps and 4 ns at 532 nm are generated by the seeded Nd:YAG regenerative amplifier or the Nd:YAG Q-switched laser.

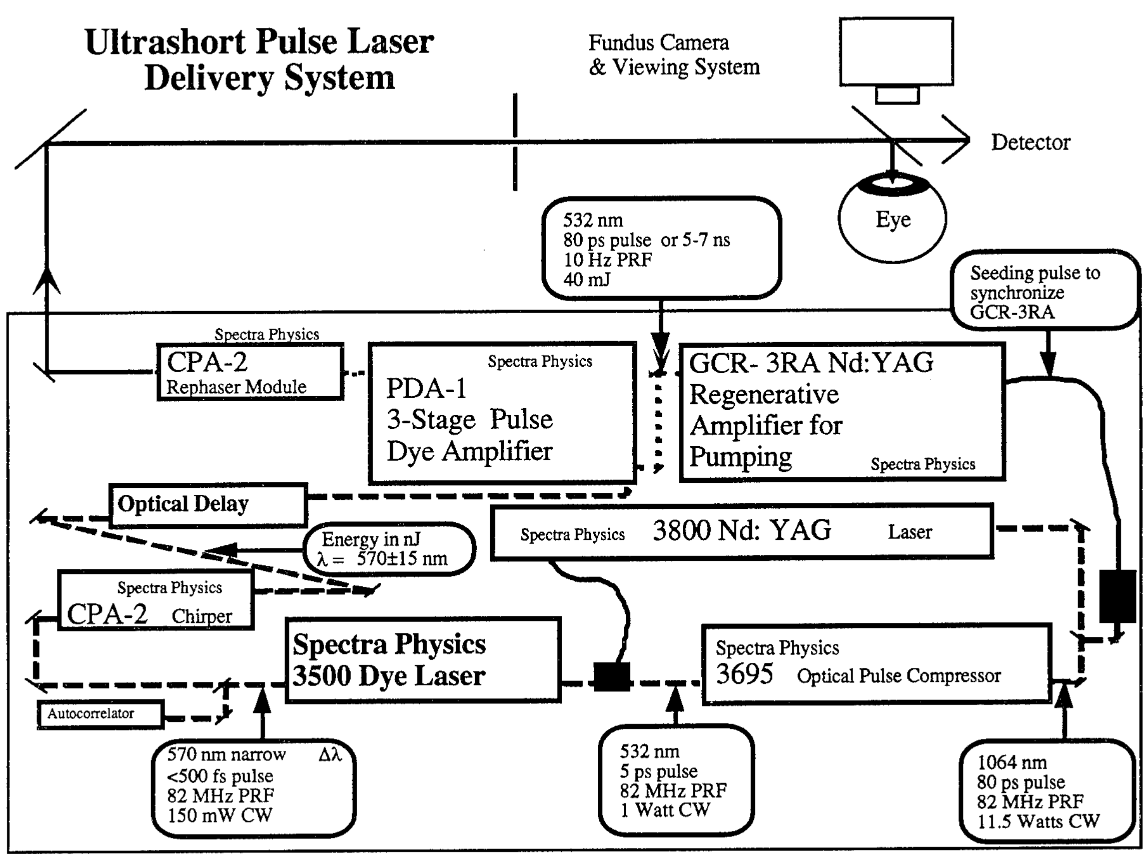

FIGURE 1. Schematic of the ultrashort laser pulse system and laser pulse delivery system.

The incident laser beam was apertured to provide a uniform spatial profile with a beam diameter of 2.5 millimeters (mm) for delivery to the corneal surface. Single pulses were delivered to monkey eyes by deflecting the beam off a glass beamsplitter (Figure 1) mounted on a Zeiss fundus camera; the beamsplitter path was adjusted such that the deflected beam was collinear with the optical axis of the fundus camera. These 580-nm beamsplitters have antireflective coatings that minimize second surface reflections and prevent double pulse generation. For suprathreshold experiments at 90 fs, the incident beam aperture was opened to 5 mm and the glass beamsplitter was replaced by a front surface mirror. The laser beam path length from aperture to incident corneal surface was 1 meter. The beam divergence was ~ 0.5 milliradian. The unamplified 580-nm mode-locked beam at 82 MHz from the pulsed dye amplifier was used to align retinal exposure sites. The output of the dye laser, 300-fs pulsewidths with 82 MHz at 580 nm and 20 to 30 milliwatts (mW), was shuttered between 100 and 200 milliseconds (ms) and used for producing retinal marker lesions.

The monkey cornea was positioned approximately 1 centimeter (cm) in front of the beamsplitter with the retina in the focal plane of the fundus camera. The single pulse was split by the 580-nm beamsplitter so that the reflected pulse could be sent to the eye while the transmitted pulse could be measured and its energy value recorded for each exposure to the eye. The reflected/transmitted (R/T) ratio was measured at the beginning and end of each session to ensure that its value did not change. Energies and ratios were measured by a joulemeter/ratiometer (Molectron JD2000 or an OM4001) with one detector (Molectron J3-09 or J4-09) at the eye position calibrated against a second detector intersecting the fraction of the beam being transmitted. Throughout this report "laser energy delivered" is the energy delivered to the corneal surface as described above and without any contact lens or other device to control the image size delivered to the retina within the eye.

***In Vivo* Model**

Mature rhesus monkeys from 2.2 to 6.9 kilograms (kg) were maintained under standard laboratory conditions (12 hours light, 12 hours dark). Rhesus monkeys were screened preexposure to ensure that no eye was more than one-half diopter from being emmetropic. All procedures were performed during the light cycle. The treatment and procedures used in this study conformed to the use of Animals in Research and Federal Guidelines and the research protocol USAFSAM Protocol RZV-91-04[12].

***In Vivo* Preparation**

Rhesus monkeys were chemically restrained using 10 milligrams (mg)/kg ketamine hydrochloride (HCl) intramuscularly. Once restrained, 0.16 mg atropine sulfate was administered subcutaneously. Two drops of proparacaine HCl 0.5%, phenylephrine HCl 2.5%, and tropicamide 1% were each administered to both eyes. Under ketamine restraint, the monkey had intravenous catheters placed for administration of warmed

lactated Ringer's solution (10 milliliters (ml)/kg/hour (hr) flow rate) and for administration of propofol. An initial induction dose of propofol (5 mg/kg) was administered to effect. The state of anesthesia was maintained in the monkey using 0.2 - 0.5 mg/kg/hr of propofol via syringe pump. The monkey was intubated with a cuffed endotracheal tube. A peribulbar injection of 2% lidocaine was administered to reduce extraocular muscular movement. The monkey was securely restrained in a prone position on an adjustable stage for the fundus photography, laser exposure, and FA. Prior to FA, 0.6 ml of Fluorescite 10% (Alcon Laboratories) was administered intravenously. The monkey's blood pressure and pulse were continuously monitored throughout the experimental protocol. The monkey's normal body temperature was maintained by the use of circulating hot water blankets.

Baseline fundus photography was performed prior to laser exposures. The eyelids were held open with a wire lid speculum, and the cornea was moistened throughout the procedures with 0.9% saline solution. The retina was viewed with a modified fundus camera through a glass beamsplitter. All macular exposures (15 to 30) were delivered to each eye, without any contact lens, in a rectangular grid pattern in the macular region of the fundus. Visible marker lesions (created by shuttered exposures of the dye laser output at 82 MHz) marked the exposure grid in columns and rows. To aid in localizing the exposure sites, an L-shaped grid pattern of marker lesions was placed around the edge of the macular region prior to the MVL exposures as shown in Figure 2. As seen within the grid pattern, there are small whitish spots just visible to the naked eye which are representative of MVLs used in the database to determine ED_{50} values. These laser exposures were delivered at 90 fs, 580 nm, with energy variations between 0.1 and 10 μJ per pulse and were placed within the grid pattern, centered over the macular region for both the left (OS) and right (OD) eyes of our subjects.

Suprathreshold lesions (greater than 10 μJ) were placed extramacularly and away from the threshold grid so that a wider scattered pattern would avoid overlapping of lesions. A minimum of two examiners evaluated all eyes at 1-hr and 24-hr postexposure. Visible lesions at a given exposure site were reported only if the two examiners identified a lesion. Fundus photography and FA were performed at 1-hr and 24-hr postexposure. Fundus photographs of ophthalmoscopically visible lesions and FAs were evaluated for lesion presentation. Two eyes were exposed with a grid of nine shots for each pulsewidth and enucleated after 1- and 24-hr postexposure for histopathological evaluations. The results of the histopathology study of the lesions will be published in a later treatise.

Fundus photography (including FA) and observations of lesion formation by the researchers were performed by monocular viewing through the Zeiss fundus camera optical system. Thus the optics were not changed between fundus viewing and photography, and viewing and photography were performed interchangeably. Photographs for FA were taken immediately before the dye injection and continued at intervals of a few seconds until five minutes had elapsed, thus providing a sequence of photographs for the development of fluorescein leakage. After fluorescein injection and

angiography, in (most) animals, lesions were also assessed for fluorescence by viewing through the camera system with excitation and barrier filter in place. However, fluorescein leakage for the smaller lesions could not be identified by this method and it was not used for this paper.

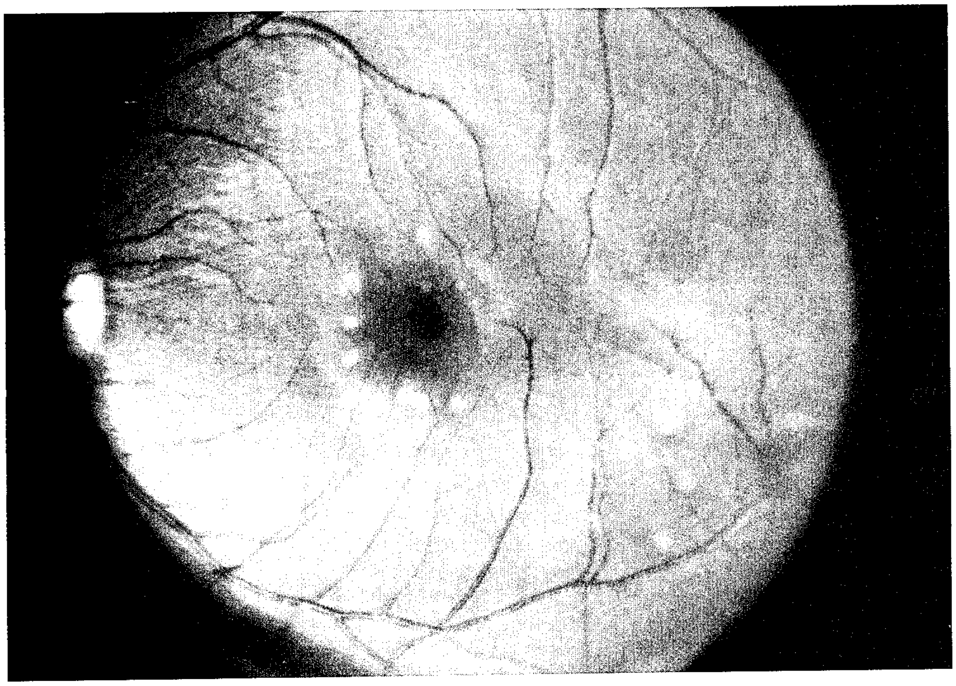

FIGURE 2. The L-shaped pattern is placed as a marker grid at the edge of the macular region. Within the grid pattern, whitish visible lesions were created using 90 fs, 580 nm, and 0.1 to 10 μJ energy pulses in the rhesus monkey eye.

Statistical Analysis

The Probit Procedure[13] was used to estimate the ED_{50} dose for creating an MVL in the retina for 4-ns, 60-ps, 3-ps, 600-fs, and 90-fs pulsewidths and to estimate the 95% confidence intervals for the ED_{50}s. Enough data was taken to ensure that the fiducial limits were reasonably narrow. The probit procedure was used for the ophthalmoscopically visible lesion data at 1 and 24 hr and for the data from the FAs. Table 1 includes the 1- and 24-hr estimated doses for ED_{50} thresholds along with the slope of the probit curve for the 24-hr reading. Also included are the number of subjects, number of eyes, and total exposures for each pulsewidth delivered. Appendix A contains the complete SAS-Probit analyses for each of the five pulsewidths together with the ordered raw data and the predicted probabilities values from 0.01 to 0.99 inclusive. The program titled SAS-PC PROBIT.NOOJIN is included for the PC version of SAS also so that any new data may be analyzed using the identical procedure.

RESULTS

Visible Lesion Thresholds

For the pulsewidths generated at 532 nm (4 ns and 60 ps), not all of the lesions developed during the first hour, and exposures at 60 ps took longer to develop than did the 4-ns exposures. The number of lesions observed increased by 25% at 4 ns and by 32% at 60 ps between the 1- and 24-hr postexposure readings. Consequently, the calculated 24-hr ED_{50} threshold dosages had to be reduced considerably for both pulsewidths as listed in Table 1. This table includes the 1- and 24-hr estimated doses for ED_{50} thresholds with the 95% fiducial intervals along with the slope of the probit curve for the 24-hr reading. The slope is calculated using the ED_{85} and ED_{50} points to obtain the values listed at each pulsewidth. Also included are the number of subjects, number of eyes, and total exposures for each pulsewidth. The retinal response to minimal exposures was consistently a pale gray to white lesion increasing in whiteness and in size as energy increased in all exposures. Exposures with energies ranging from (0.03 - 6.6 μJ) for both pulsewidths were placed macularly. For the 4-ns study, two eyes from two different monkeys were used for a total of 50 exposures in the macular region. At 60 ps, five eyes from five different monkeys were exposed, with 88 total exposures in the macula. Color fundus photographs for the these pulsewidths showing typical lesions in the macular region are included in Appendix B.

TABLE 1. Minimum Visible Lesions Threshold - ED_{50} for Rhesus Monkeys at the 95% Confidence Level with Fiducial Limits in Parentheses.

PULSEWIDTH	1 HOUR READING ED_{50} (μJ)	24 HOUR READING ED_{50} (μJ)	SLOPE OF PROBIT CURVE
4 ns 2 Subjects, 2 Eyes, 50 Exposures	1.5 (0.75 - 8.93)	0.9 (0.60 - 1.35)	2.68
60 ps 5 Subjects, 5 Eyes, 88 Exposures	0.66 (0.46 - 1.05)	0.43 (0.32 - 0.54)	3.03
3 ps 4 Subjects, 4 Eyes, 68 Exposures	0.68 (0.40 - 0.91)	0.58 (0.31 - 0.83)	2.61
600 fs 5 Subjects, 6 Eyes, 112 Exposures	0.60 (0.43 - 0.84)	0.26 (0.21 - 0.31)	4.11
90 fs 5 Subjects, 7 Eyes, 122 Exposures	1.18 (0.83 - 2.09)	0.43 (0.27 - 0.60)	1.58

For the pulsewidths evaluated at 580 nm (3 ps, 600 fs, and 90 fs), the delay in the appearance of a visible lesion to minimal retinal laser exposures depended on the pulse energy and on the pulsewidth. The retinal response to these exposures was consistently a pale gray to white lesion increasing in whiteness and in size as energy increased as before. At 3 ps, threshold retinal lesions were visible almost immediately; 98% were visible after only 1 hr. The range of energies (0.45 μJ to 1.43 μJ) producing a visible lesion did not change between the 1- and 24-hr evaluations. Color fundus photographs for typical lesions at these three pulsewidths are included in Appendix B.

For 600-fs pulsewidths, the time required for a lesion to appear increased significantly; only half were visible after 10 minutes. From the 1-hr reading to the 24-hr reading, we observed an increase of 30% in the number of visible lesions at a given exposure level. The MVL ED_{50} threshold dosage calculated for 24 hr was less than half the value calculated for 1 hr. Also, the range of pulse energies from minimum-to-maximum (minimum lesion to maximum no-lesion) decreased significantly from the 1-hr reading to the 24-hr reading (0.22 μJ - 3.0 μJ to 0.17 μJ - 0.45 μJ).

At 90-fs pulsewidths, the delay in appearance of visible lesions past the 1-hr reading was even more pronounced, and the calculated ED_{50} values were larger than the 600-fs values for both the 1-hr and 24-hr calculations. Again, the ED_{50} dosage calculated at 24 hr was less than half the value at 1 hr, showing that a large number of lesions (28) developed between 1 hr and 24 hr. In fact, a 48% increase in the number of visible lesions (58 to 86) occurred at the 24-hr reading. The range of energies from minimum-to-maximum did not change significantly during the 24-hr postexposure examinations (0.16 μJ-1.8 μJ to 0.10 μJ-1.4 μJ). Above 1.4 μJ, all energies delivered showed visible lesion development. Out of 122 data points taken at 90 fs within the macula, 94 exposures were within the energy range of 0.1 μJ to 1.4 μJ, and 49 lesions developed within 24 hours. For 3 ps, four monkeys and four eyes were used for a total of 68 exposures. For 600 and 90 fs, six monkeys were used for each pulsewidth with six eyes exposed with 112 exposures and seven eyes exposed with 122 exposures respectively as listed in Table 1.

In our studies, FA appeared to be much less sensitive in identifying retinal lesions than determining the lesions ophthalmoscopically. This insensitivity occurred across all readings for our pulsewidths, wavelengths, and observation times. At 3 ps, the fluorescein angiography visible lesion (FAVL) ED_{50} value dropped from 2.8 μJ at 1 hr to 1.3 μJ at the 24-hr readings. However the FAVL ED_{50} values were much higher than the ophthalmoscopically determined MVLs. For the 600-fs pulses, the FAVL ED_{50} value dropped from 3.7 μJ to 1.5 μJ after 24 hr. These values are six times higher than the MVLs read funduscopically. In each case the 24-hr reading was lower than the 1-hr reading. This was not the case with 90 fs, where the 24-hr calculated FAVL ED_{50} thresholds were more than 1.6 times the value at 1 hr and more than 6.7 times the MVL ED_{50} value. Using FA as an endpoint, the trend of more lesions showing up after 24 hr dramatically reversed at 90 fs, and many of the lesions counted after 1 hr simply disappeared during the post 24-hr FA evaluation. Although, the number of

funduscopically visible lesions increased from 58 to 86 at 24-hr postexposure, the number of lesions showing up on FA decreased from 43 at 1 hr down to 25 after 24 hr. The data for our FA work are given in Table 2 along with the MVL ED_{50} values for comparison. Black and white fundus photographs for the FA have been included in Appendix B for all 5 pulsewidths for each primate eye which have color fundus photographs showing visible lesions.

TABLE 2. Fluorescein Angiogram Minimum Visible Lesion Threshold - FAVL ED_{50} for the Rhesus Monkey Compared to ED_{50} MVL.

PULSEWIDTH		1 HOUR READING (μJ)	24 HOUR READING (μJ)
4 ns	FAVL	*	1.8 (1.2 - 3.7)
532 nm	MVL	1.5	0.9
60 ps	FAVL	1.9 (1.1 - 10.1)	1.5 (0.98 - 4.4)
532 nm	MVL	0.66	0.43
3 ps	FAVL	2.8 (2.1 - 4.7)	1.3 (1.0 - 1.6)

*Data not at 95% confidence level.

Hemorrhagic Lesion Thresholds

In the rhesus monkey, laser exposures at 90 fs were directed to the macula for lesions created with energies under 10 μJ. All laser exposures exceeding this value were directed away from the macula, most of which were directed nasal to the optic disc, and a few were directed outside the temporal arcades. Of the 122 exposures (0.01 to 9.3 μJ) delivered to the macula at 90 fs, seven hemorrhagic lesions were produced with 0.83 to 4.8 μJ energy (2 to 11 times MVL ED_{50} of 0.43 μJ). While delivering energy within the macular grid pattern, the laser would infrequently intersect the network of retinal microvessels. Macular hemorrhagic lesions were seen only when the exposure site coincided with a small blood vessel. The area of the hemorrhages was approximately 50 to 250 micrometers (μm) in diameter (estimated relative to the optic nerve and vessel size in photographs), and they were either thin with lacy margins or very slightly thickened with smooth round margins. The hemorrhage location appeared to be intraretinal for several lesions; however, without stereo imaging, it was difficult to differentiate small intraretinal versus subretinal hemorrhages. With FA, the blood from the macular hemorrhages blocked fluorescence from both the underlying retinal vessel and the choroid.

At one of the sites there was late fluorescein leakage from the margin of the hemorrhage. While many hemorrhages appeared almost immediately, three hemorrhages in one eye, not visible immediately after laser exposure, developed within 1 hr and increased in size over the next 24 hr. These same hemorrhagic lesions were not visible ophthalmoscopically, 29 days after laser exposure. All data for hemorrhagic versus nonhemorrhagic lesions has been summarized in Table 3 for all exposures and pulsewidths.

TABLE 3. Hemorrhagic Lesions Produced in Rhesus Monkey Eyes for all Pulsewidths and Pulse Energies.

PULSEWIDTH	ENERGY DELIVERED TO CORNEA (μJ)	HEMO. LESIONS	NONHEMO. LESIONS	TOTAL LESIONS	TOTAL EXPOS.
90 fs	0.01 - 9.3	7	63	70	122
	ext.macular - (14 - 105)	5	17	22	(22)
600 fs	0.02 - 15.5	7	64	71	112
	ext.macular -(2)	3			(3)
3 ps	0.03 - 11.4	6	41	47	68
60 ps	0.03 - 6.6	1	49	50	88
4 ns	0.09 - 5.0	0	25	25	50

Of 21 suprathreshold energy exposures (14 to 105 μJ) at 90 fs and 580 nm placed outside the macula, five hemorrhagic lesions were produced by energies ranging from 38 to 105 μJ. One of these lesions demonstrated a very faint (less than 50 μm) red lesion ringed by a white chorioretinal lesion. Three lesions were probably subretinal hemorrhages (although intraretinal blood leakage from retinal vasculature is possible) of approximately 50 to 100 μm diameter with a rim of white chorioretinal thickening. One laser site (81 μJ) over a retinal venule demonstrated an immediate retinal hemorrhage which enlarged over 24 hr. With FA, the injured retinal vessel demonstrated leakage within the area of blocked fluorescence from the hemorrhage.

Sixteen suprathreshold lesions (14 to 82 μJ) were nonhemorrhagic even though the laser energy for several of these was delivered directly to overlying retinal blood vessels. The lesions were white and, as with rabbit lesions[8], their size increased as pulse energy increased.

For the 600-fs pulses, a total of 112 exposures were placed within the macula, all had energies between 0.02 μJ and 15.5 μJ. Seven of fourteen exposures with energies ranging from 3.6 μJ to 15.5 μJ, produced hemorrhagic lesions in the macular region. Three exposures with energies of 2.1 μJ were placed nasal to the optic disc and all three produced hemorrhages. All lesions produced at this pulsewidth appeared to be in intraretinal vessels; none were believed to be choroidal hemorrhages. Similar results were found at 3-ps pulses where six hemorrhagic lesions were produced in the macula by energies ranging from 1.6 μJ to 11.4 μJ; all were intraretinal hemorrhagic lesions. All hemorrhagic lesions produced in the macula were counted as positive lesions in the MVL data pool because they were always visible funduscopically.

At the 4-ns pulsewidth there were no hemorrhages produced for pulse energies ranging up to 5 μJ within the macular area. At the 60-ps pulsewidth, there was only one hemorrhage produced with 6.6 μJ intraretinally; no attempt was made to produce hemorrhages with suprathreshold doses. Of the 88 total exposures for 60 ps and 532 nm, only one pulse had an energy greater than 4.1 μJ and it produced a hemorrhage. All pulses within the range of energies used (0.03 μJ - 6.6 μJ) for both pulsewidths were placed within the macular area; no attempt was made to create hemorrhages within or outside of the macular area with suprathreshold energies.

DISCUSSION

We have determined the MVL thresholds for laser pulsewidths from 4 ns down to 90 fs. As listed in Table 1, all ED_{50} values are below 1.0 μJ with the exception of the 1-hr readings at 4 ns and 90 fs. In assessing the implications of retinal laser damage observed in this study, we consider biological and laser variables which impact the damage thresholds measured. The biological variables which affect ED_{50} include species, ocular anatomy, retinal lesion location, retinal vasculature, pigmentation of the retinal pigment epithelium, and choroid. This study is the first to report lesions in primate eyes for pulsewidths from 4 ns down to 90 fs; it is directly comparable to all other data reported for the primate eyes down to 6 ps, including the data from which the ANSI Z136.1-1993[1] standard is derived.

The laser variables which impact the determination of retinal damage thresholds include wavelength, pulse duration or pulsewidth, beam diameter incident upon the cornea, beam profile, retinal spot size, beam divergence, and optics used in the pulse delivery. One benefit from our study is the evaluation of a wide range of laser pulsewidths using the same species and delivery system. The change in MVL thresholds identified in our study for the five pulsewidths and two wavelengths suggests that the calculated ED_{50} thresholds depend not only on pulsewidth, but on the wavelength as well, which one would expect to be the case.

For the two pulsewidths at 532 nm, 4 ns and 60 ps, the number of lesions observed between the 1-hr reading and the 24-hr reading increased between 25% and 32% which

had the effect of lowering the MVL ED_{50} threshold doses calculated by probit analyses. At 4 ns, the threshold dose decreased from 1.5 μJ to 0.9 μJ after 24 hr while the value at 60 ps decreased from 0.66 μJ to 0.43 μJ after 24 hr. The slope of the probit curve increased from 2.68 to 3.03 when the pulsewidth was reduced from 4 ns to 60 ps while the ED_{50} decreased from 0.9 μJ to 0.43 μJ, respectively. However, these slopes are larger than those reported by Lund and Beatrice[14] (1.58 for the slope of the regression line defined as ED_{84}/ED_{50}) for doubled Nd:YAG pulses at 140-ns pulsewidths.

Ophthalmoscopically, the time interval for development of retinal MVLs for the 580-nm wavelength increased significantly for 600 and 90 fs as with 4 ns and 60 ps, but this was not true for the 3-ps case. For 600 fs, there were 21 exposures between 0.17 and 3.0 μJ, which required more than 1 hr to develop out of a total of 112 exposures. These delayed lesions reduced the MVL ED_{50} threshold dosage calculations from 0.60 μJ (1 hr) to 0.26 μJ (24 hr) with reduced fiducial limits as well. At 90 fs, there was a 48% increase in the number of visible lesions after 24 hr as compared to the 1-hr reading. For 90 fs there was a total of 34 exposures, with dosages ranging between 0.10 and 2.0 μJ, which required longer than 1 hr to develop into visible lesions. These additional lesions reduced the calculated MVL ED_{50} threshold values from 1.18 μJ (1 hr) to 0.43 μJ (24 hr); there was a similar reduction in the fiducial limits.

The slope of the probit curve at 3 ps was almost identical to that at 4 ns, but then it changed greatly as the pulsewidth was reduced down to 90 fs. The value at 600 fs was more than 150% (4.11) the value at 3 ps, but then the slope dropped to 60% of the 3 ps value at 90 fs. We attribute this large swing up and then down to the multiple effects of nonlinear propagation and self-focusing within the eye at these shortest pulsewidths. Rockwell et al.[15,16] have measured the nonlinear index of refraction in vitreous humor and they have developed a simplified model to predict the self-focusing effects for light propagating in the eye. Their model predicts a critical peak power within the laser pulse propagating through the vitreous at which the focused image collapses (beam collapse) into a filamentary propagating beam as predicted by Powell et al.[17] When we compare the peak power in our pulses for the MVL ED_{50} value in Table 1, we find that the value at 600 fs is just below the critical peak power of 500 kilowatts (kW), and the value at 90 fs is an order of magnitude above the critical power. Thus we expect that the self-focusing effects without beam collapse at 600 fs should lower the threshold MVL ED_{50} values because of a smaller retinal image size. Also, it is possible for the beam to collapse at 90 fs; this collapse could cause nonlinear effects to occur within the vitreous or retinal layers. Laser-induced breakdown could occur anterior to the retina and produce a shock wave causing mechanical damage to the neural layer. This type of damage may prevent leakage and thus would not show up in FA which would increase the calculated threshold dose. Nonlinear effects due to beam collapse could also prevent some of the energy in the pulse from reaching the retina and increase the MVL ED_{50} threshold dose above those for longer pulsewidths whose peak power levels are much lower than the critical power.

In search for a damage model which would fit our data, several models were considered and some were rejected outright because they could not adequately describe our findings. As an example, when we consider the thermal model usually ascribed to damage from longer pulsewidths (i.e, greater than 1 ns), we calculated the temperature rise for all our pulsewidths below 1 ns and found the ΔT to be $14^{\circ}C$ or less. These calculations are based on an image diameter of 30 μm and a pigmented epithelium (PE) 10-μm thick with all of the energy reaching the retina being absorbed in this layer. Thus we reject the thermal model to describe our damage thresholds because the temperature-time history is not even close to being adequate to cause damage.

Photochemical damage processes as discussed by other researchers[3-5] for the picosecond pulsewidths appear to be possible damage mechanisms because of the latency of the development of lesions. In all cases our threshold dose at 24 hr was lower than at 1 hr which suggests either photochemical damage or possibly mechanical damage due to acoustic or shock waves. Our histopathological results will, when they become available, help us to better describe the damage mechanisms.

Another damage mechanism which we cannot reject, especially for the femtosecond pulses, is the possibility of direct membrane effects resulting from the intense electric fields associated with these pulses.[4,5] The peak power going into the eye at the ED_{50} threshold at 90 fs was 5 megawatts (MW) and thus the peak irradiance at the retina was well up into the GW/cm^2 (gigawatts) range. With such extremely high retinal irradiances, retinal cell damage would be most likely to occur which would agree with the latency of the observed injury.

In determining ED_{50} threshold levels for rhesus monkeys, our FA studies did not show the sensitivity that our direct ophthalmoscopic examinations did. With probit calculations for the 1-and 24-hr readings for the five pulsewidths studied, there were seven instances when the fiducial confidence intervals did not overlap, and only two in which they did. The exceptions were 90-fs thresholds at the 1-hr reading (2.09 μJ MVL versus 1.2 μJ FAVL) and the 24-hr reading at 4 ns (1.35 μJ MVL versus 1.2 μJ FAVL). However, the FAVL ED_{50} decreased between the 1- and 24-hr readings for all pulsewidths with the exception of the 90 fs, for which it increased by almost 60%. Thus, many of the FA lesions visible at 1-hr postexposure at 90 fs disappeared and were not visible after 24 hr. These findings contrast with other FA work including our own in dutch-belted rabbits[11] where at 5 ps, 500 fs, and 90 fs the MVL to FAVL ratios for 1-hr postexposure were 1.2, 2.8, and 3.7, showing greater sensitivity in FAs respectively. The same procedure was used in determining our FAs for the rhesus monkey in this study. With observation, and with analysis of fundus photographs and FAs, we found FA to be unreliable in identifying the small, barely above threshold lesions at short pulsewidths. The choroidal pattern of fluorescence could not be differentiated from the minimally fluorescent less-than-30-micron lesions in these cases. Also, we enlarged our FAs photographically by 5 to 1 in comparison to the strip photographs and found no significant change in our ability to read lesions.

Birngruber et al.[7] noted fluorescein angiography to be more sensitive than observation of minimal short pulse laser lesions; however, they artificially maintained a constant lesion size of 50 microns in a rabbit eye. In addition, their fluorescein ED_{50} was 0.75 μJ while our MVL ED_{50} was only 0.43 μJ, a little more than half of their value for fluorescein and less than one-tenth of their visible lesion threshold of 4.5 μJ. This difference can be accounted for by the difference in image size as well as the different species (i.e, primate versus rabbit).

Borland et al.,[18] with 15- and 40-ns lesions, noted a similar problem with FA of small laser lesions. As reported in 1978, the granular appearance of the fluorescein "was of the same order as the small size lesions: 10-30 microns," and "small image lesions were extremely difficult to identify at just suprathreshold exposure levels." When they plotted the regression lines of the probit curves, they identified a reduction in statistical reliability with FA because of the confusion between threshold lesions of small image size and the background grain of the choroidal flush for minimal image size exposures. In our study, not only do we have minimal size lesions in which we would expect a reduction of fluorescein reliability for the same reasons mentioned above, but we also have shorter pulse lesions which should produce less thermal area of damage. As Borland's group observed, thermal damage with disruption of zona occludentes and cell walls was associated with FA positive lesions. A histopathologic study of our ultrashort-pulse lesions will provide additional insight into our findings in the future.

CONCLUSION

Our data for the rhesus monkey can be compared with other published data as included in the database used to establish the ANSI Z136.1-1993[1] standard, shown in Figure 3. The only known data points for rhesus monkeys for pulsewidths below 1 ns at visible wavelengths are also shown in Figure 3 (Goldman et al.[3] and Bruckner and Taboada[5]). Because Goldman et al. did not do a probit study, our data is more directly comparable to the Bruckner and Taboada datum point at the 6-ps pulsewidth. At 4 ns and below, our ED_{50} thresholds for the 24-hr readings (within the circles) for rhesus monkeys show a slight downward trend until 90 fs is reached; then the estimated value becomes larger. This abrupt change in slope may be due to nonlinear effects such as self-focusing and/or beam collapse due to the high peak powers at 90 fs. The solid black line shown in Figure 3 represents the ANSI retinal MPE for pulsewidths down to 1 ns which is 0.5 $\mu J/cm^2$. Thus, 0.2 μJ at the cornea for a pulsewidth of 1 ns is considered safe; however, one cannot extrapolate this safe level to pulsewidths below 1 ns because our data includes nine visible lesions out of a total of 54 exposures at or below 0.2 μJ for pulsewidths below 1 ps (90 fs and 600 fs). However, below 1 ns, ANSI recommends a constant irradiance for decreasing pulsewidths and therefore at 100 fs, the safe limit would only be 20 picojoules (pJ), or more than four orders of magnitude below our MVL ED_{50}. It is obvious from Figure 3 that our MVL ED_{50} thresholds are an order of magnitude or more below those in the databank for pulsewidths longer than 1 ns and do not decrease with

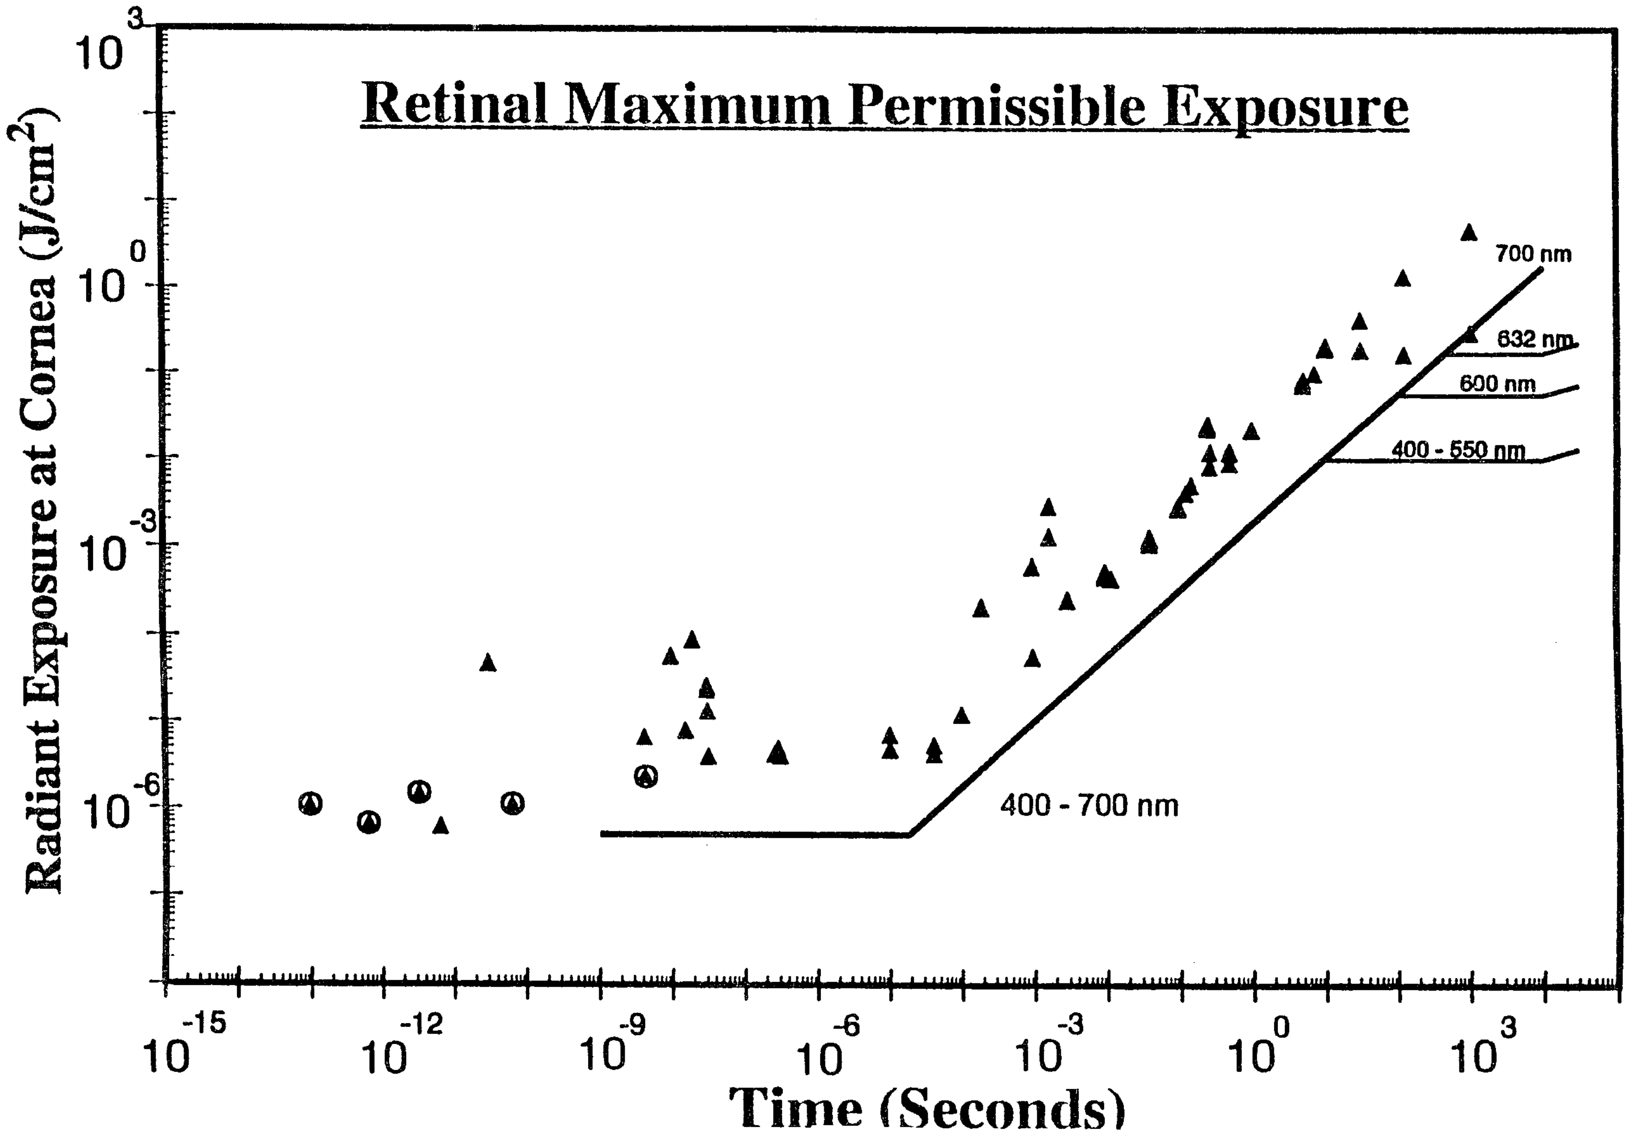

Figure 3. Retinal maximum permissible exposure for ANSI Z136.1-1993. The solide line indicates the current National Standard below which radiant exposure levels are considered safe. The triangles represent the database upon which the standard is determined and the circled triangles are from the present study.

pulsewidth to an appreciable extent. Therefore new interim standards could be set for picosecond and femtosecond laser pulsewidths which would relax somewhat the constant irradiance for decreasing pulsewidths ANSI recommendation. These interim standards could apply until the histological studies are completed and the damage mechanisms are fully understood. until the histological studies are completed and the damage mechanisms are fully understood. New standards are especially critical because laser systems which produce tens of millijoules per pulse below 100-fs pulsewidths are now commercially available. These pulses can have energies as much as five orders of magnitude greater than necessary to create visible lesions in the eye.

APPENDIX A

This appendix contains the SAS-PC Probit Procedure program used in the data analysis and all minimum visible lesion data for all five pulsewidths, both visible lesion data and fluorescein angiographic data. In addition to the raw data in ordered format, the probability plot and the predicted distribution of doses between 0.01 and 0.99 probability are included along with 95% confidence level for the fiducial intervals.

L.R. Chi-Square	54.7453	79	0.9829

Response Levels: 2 Number of Covariate Values: 81

WARNING: All variances and covariances have been multiplied by the heterogeneity factor H= 2.4746. Please check to be sure that the large chi-square (p < 0.0001) is not caused by systematic departure from the model. A t value of 1.9905 will be used in computing fiducial limits.

APPENDIX B

This appendix contains fundus photographs showing visible lesion development and fluorescein angiography for a least one eye at each pulsewidth. The order of pulsewidths is from lowest to highest with the color visible lesion photograph first at 1 and 24 hours and then the FA photographs at 1 and 24 hours also.

Order of Photographs

Monkey #639-OD		
Figure A.	90 fs-580 nm	1-hour color fundus photograph
Figure B.		24-hour " "
Figure C.		1-hour fluorescein angiography
Figure D.		24-hour " "
Monkey #775-OS		
Figure A.	90 fs-580 nm	1-hour color fundus of suprathreshold lesions
Figure B.		24-hour " " "
Figure C.		1-hour fluorescein angiography

Figure B.		24-hour " "
Figure C.		1-hour fluorescein angiography
Figure D.		24-hour " "

639-OD

Figure A. (90 fs-580 nm) One-hour fundus photograph showing L-shaped marker grid surrounding MVL exposure sites. The 16 threshold data lesions range in energy of delivery from 0.52 to 4.8 μJ. Three hemorrhagic lesions occurred at 1.7 to 4.8 μJ, and became apparent ophthalmoscopically within 10 minutes.

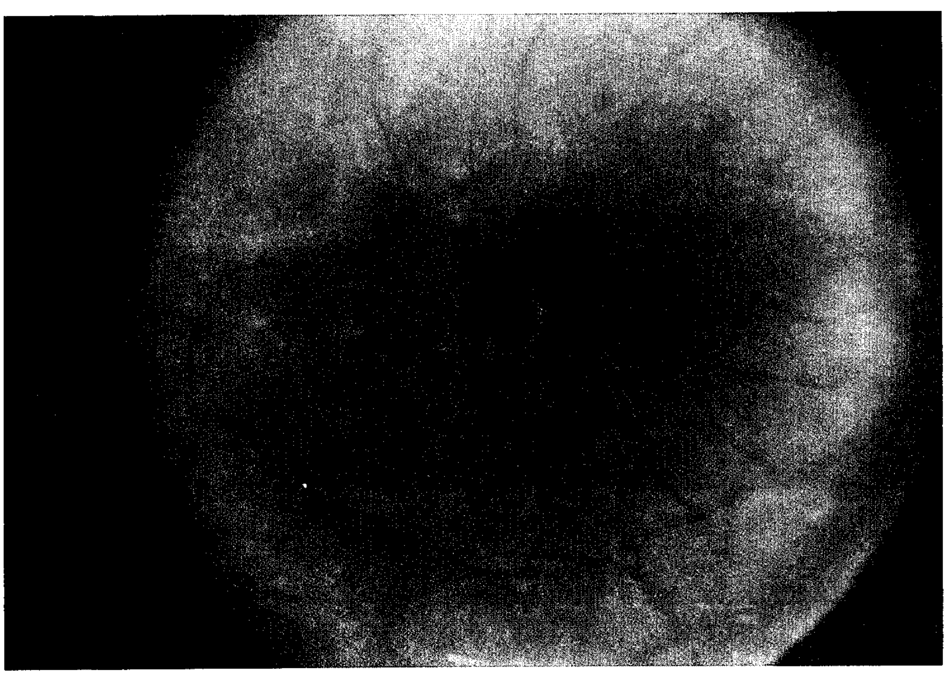

Figure B. 24-hour fundus photograph shows increase in the area of blood leakage from 3 hemorrhages, and more apparent whiteness from MVLs.

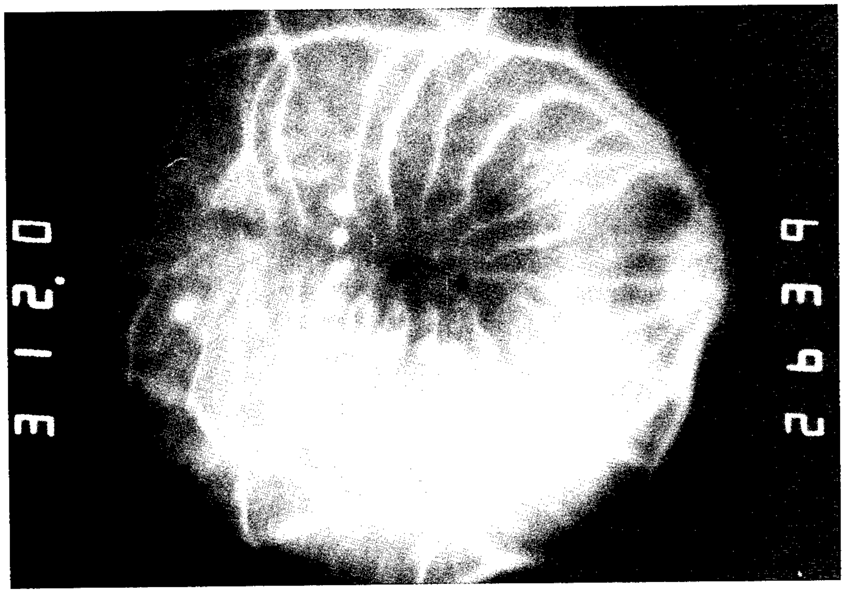

639-OD
Figure C. (90 fs-580 nm) One-hour FA showing lesions that demonstrate hyperfluorescence except where blocked by blood.

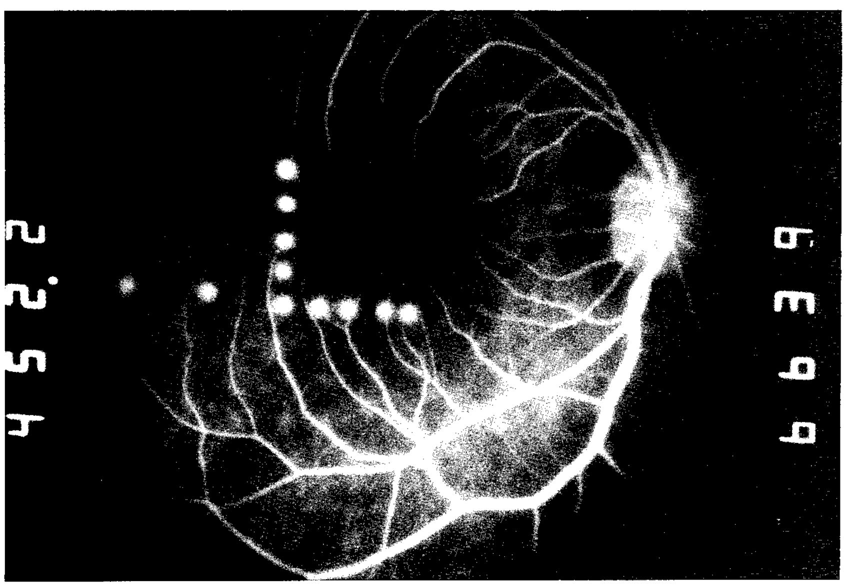

Figure D. 24-hour FA demonstrates fewer lesions that hyperfluoresce compared to those at 1 hour.

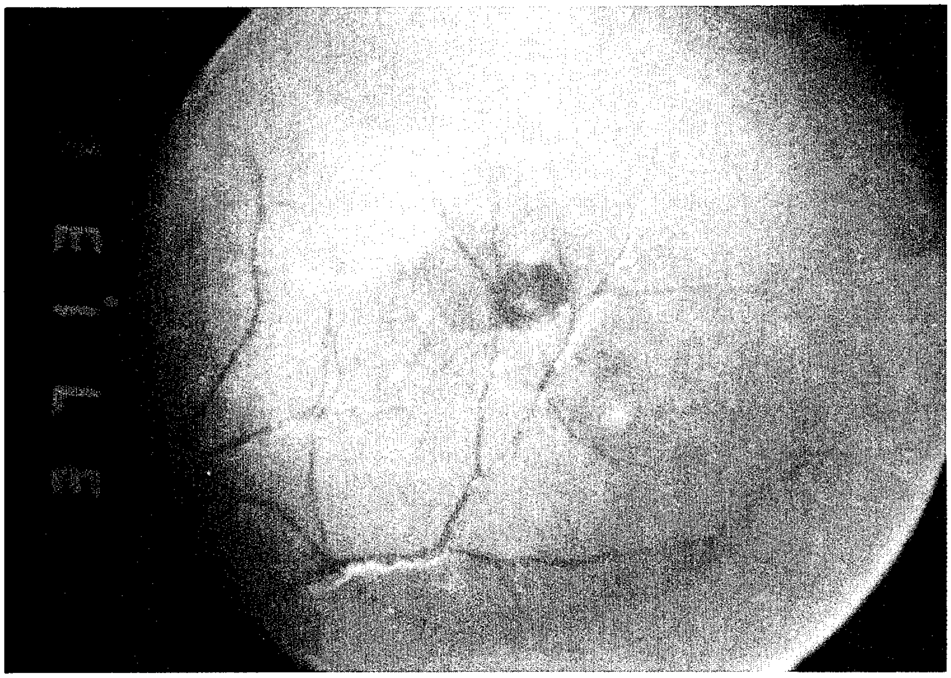

775-OS
Figure A. (90 fs-580 nm) One-hour fundus photograph of 6 suprathreshold lesions delivered from 22 to 82 μJ of energy. The hemorrhagic lesion in the macula occurred over a retinal venule with energy delivery of 81 μJ.

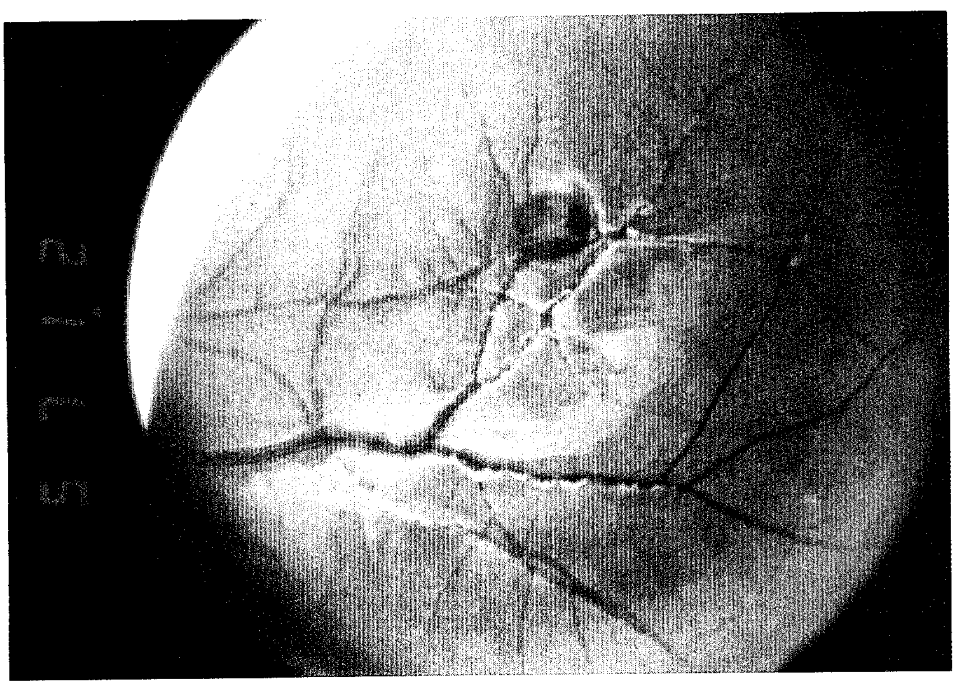

Figure B. 24-hour fundus photograph showing an enlargement of the 81 μJ hemorrhage as well as the non-hemorrhagic suprathreshold lesions

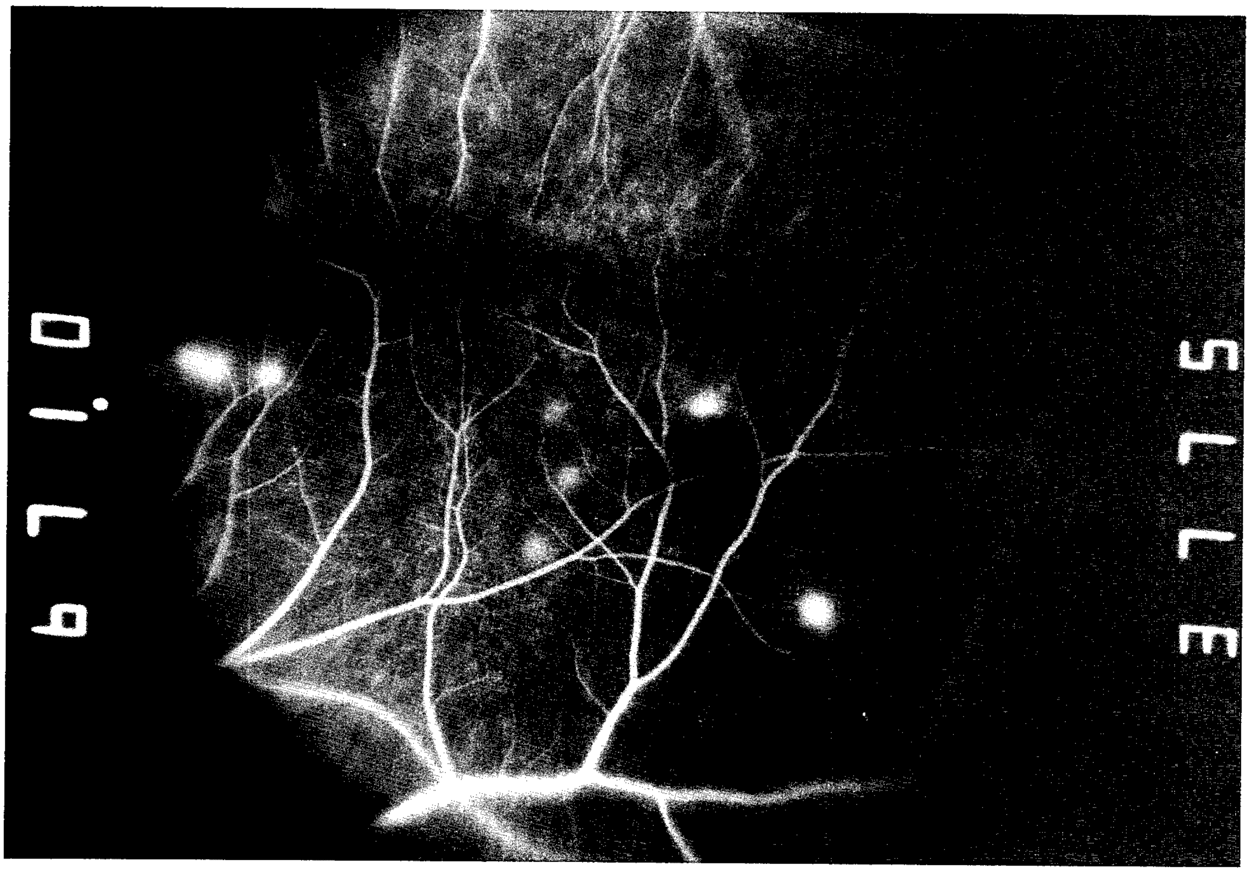
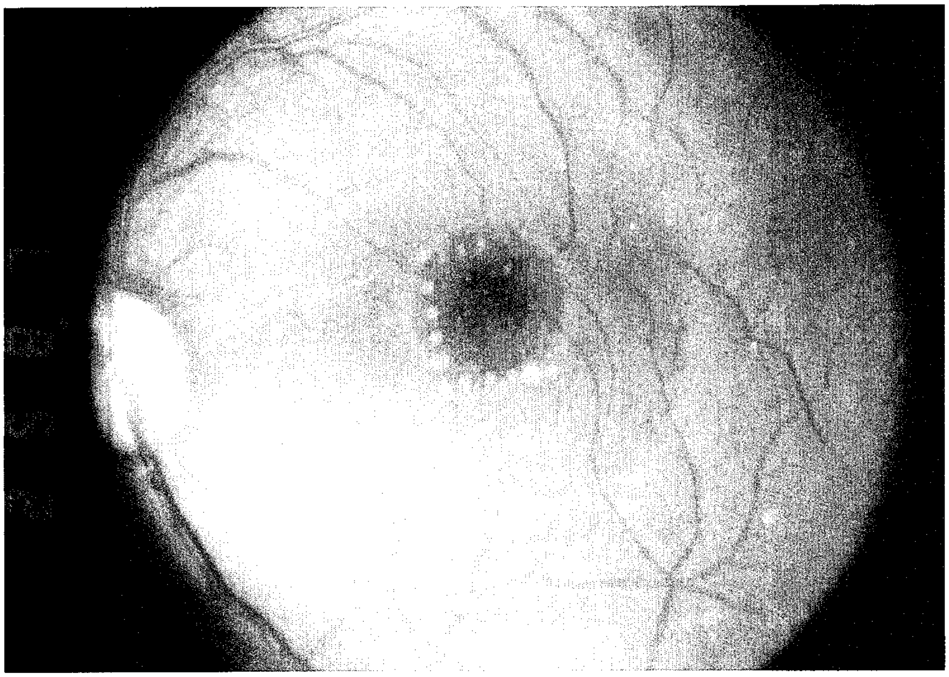


775-OS
Figure C. (90 fs-580 nm) One-hour flourescein angiogram (FA) showing hyperfluorescence from the non-hemorrhagic suprathreshold lesions, and leakage within the area of blocked fluorescence from the site of the hemorrhage.



639-OS
Figure A. (600 fs-580 nm) One-hour fundus photograph of 25 threshold lesions ranging from 0.10 to 10.2 μJ. Three hemorrhagic lesions occurred between 3.6 to 10.2 μJ and became apparent ophthalmoscopically within 10 minutes.

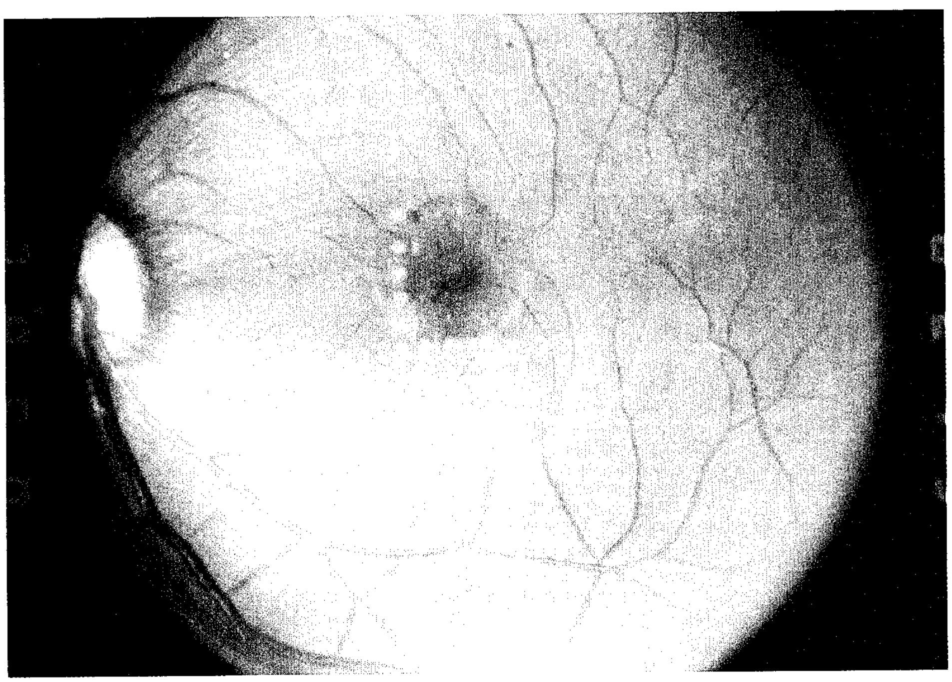


Figure B. 24-hour fundus photograph showing an increase in size of the 3 hemorrhages between 1 and 24 hours.

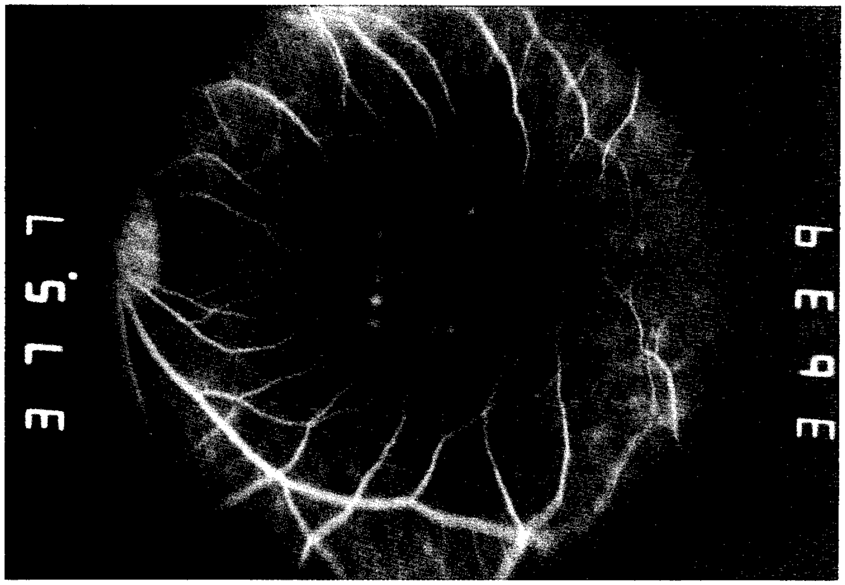

639-OS
Figure C. (600 fs-580 nm) One-hour FA showing a few sites of visible fluorescein leakage or blockage.

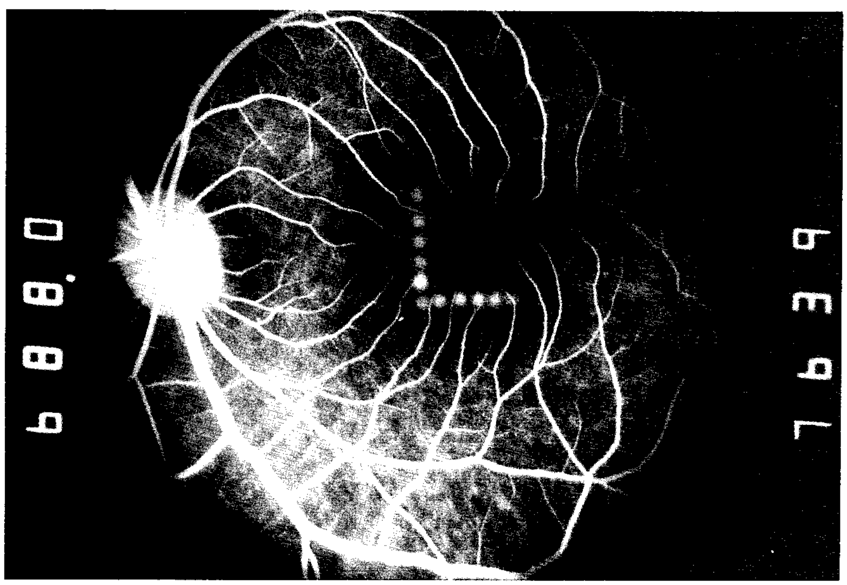

Figure D. 24-hour FA showing that more lesions are visible than in the 1 hour FA. This demonstrates that lesion development between 1 and 24 hours increased significantly. However, fewer lesions are visible in the 24-hour FA compared to the 24-hour fundus photograph, implying that fluorescein angiography is less sensitive than ophthalmoscopic evaluation.

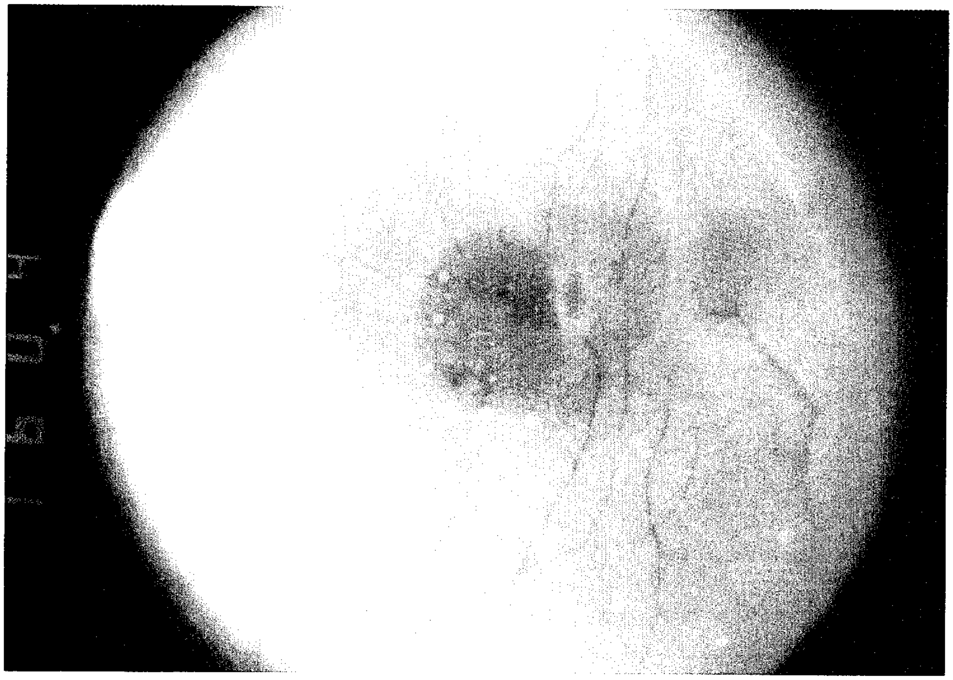

589-OS
Figure A. (3 ps-580 nm) One-hour fundus photograph of 9 threshold lesions ranging in energy of delivery from 0.45 to 9.5 μJ. One hemorrhagic lesion occurred at 9.5 μJ and became apparent within 10 minutes.

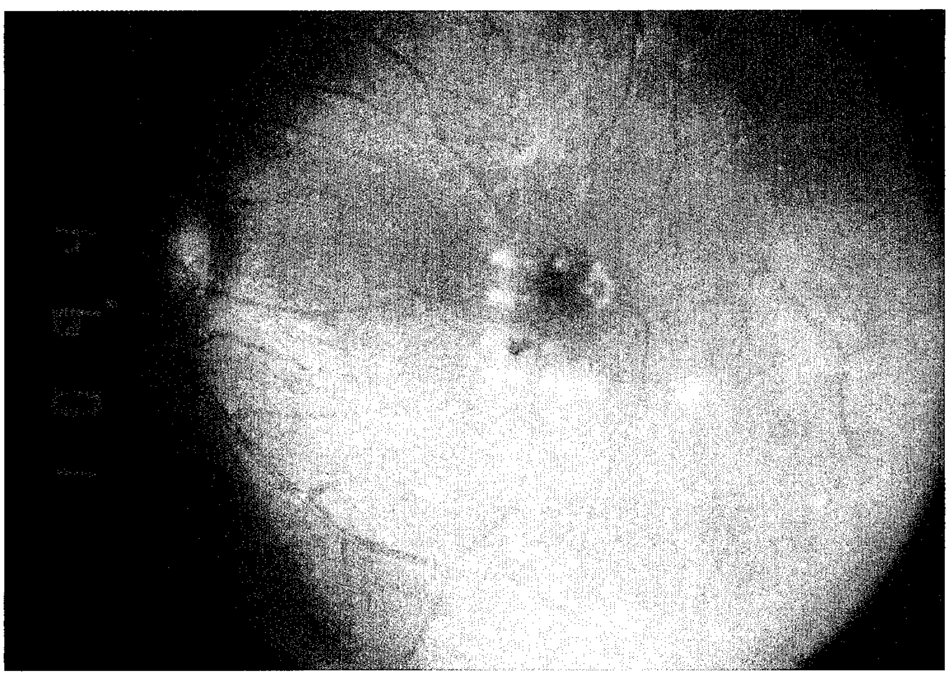

Figure B. All lesions became ophthalmoscopically visible within 24 hours.

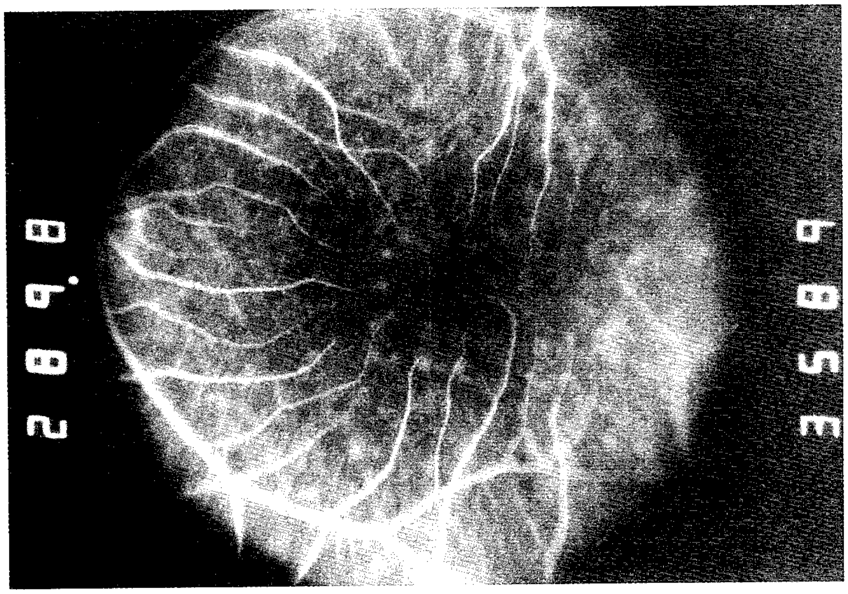
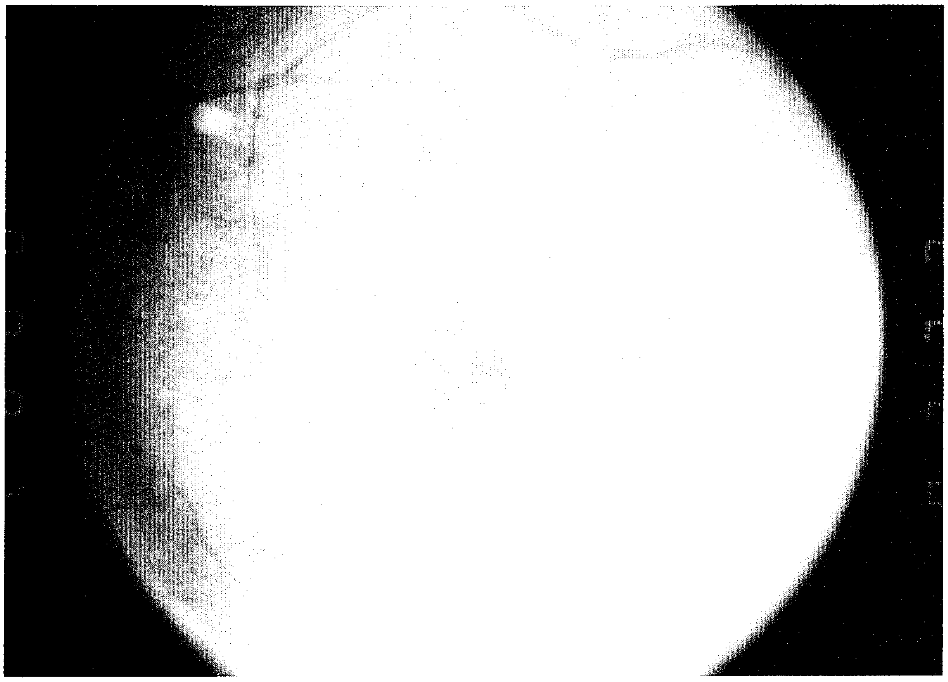


589-OS
Figure C. (3 ps-580 nm) One-hour FA showing the site of blocked fluorescence corresponding to the 9.5 μJ hemorrhage. Fewer lesions are apparent (as compared to Figure A.) showing a decrease in sensitivity FA compared to ophthalmoscopic evaluation. No hyperfluorescence marking the 1.7 to 5.3 μJ lesions is apparent by fluorescein angiography, although it was ophthalmoscopically visible at 1 hour.

Figure D. At 24 hours, FA determination shows all lesions in the middle row and the 1.4 μJ lesion (previously visible ophthalmoscopically) do not hyperfluoresce while all others emit a faint hyperfluorescence.



773-OD
Figure A. (60 ps-532 nm) One-hour fundus photograph of 9 lesions ranging in energy of delivery from 0.26 to 3.7 μJ. All lesions in the bottom row and the 2 lesions at 0.85 and 0.86 μJ became apparent within 1 hour.

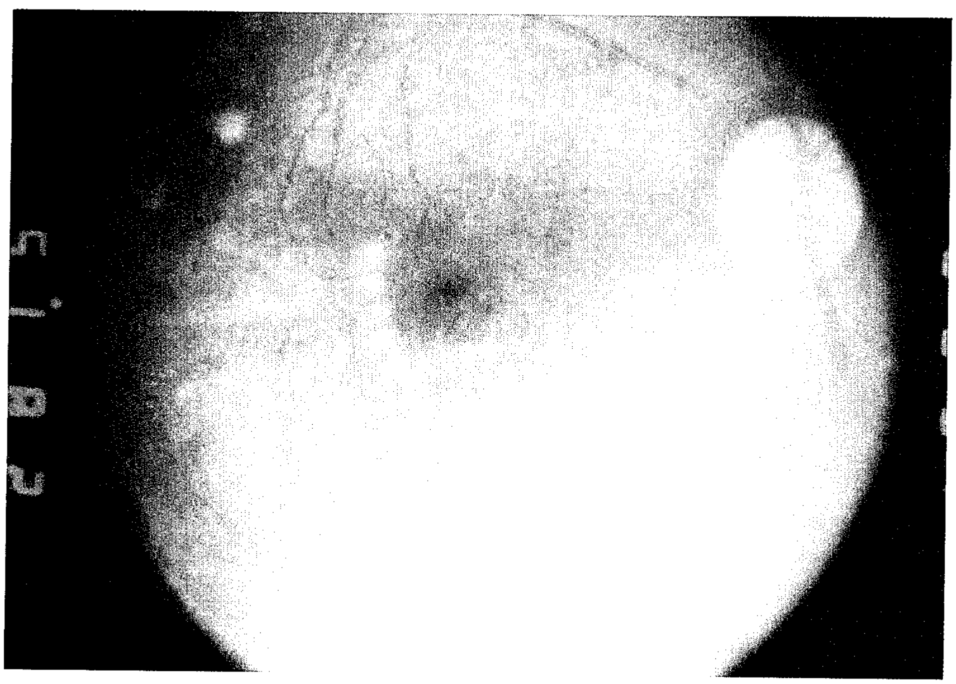


Figure B. At 24 hours, all lesions in the second row became ophthalmoscopically visible.

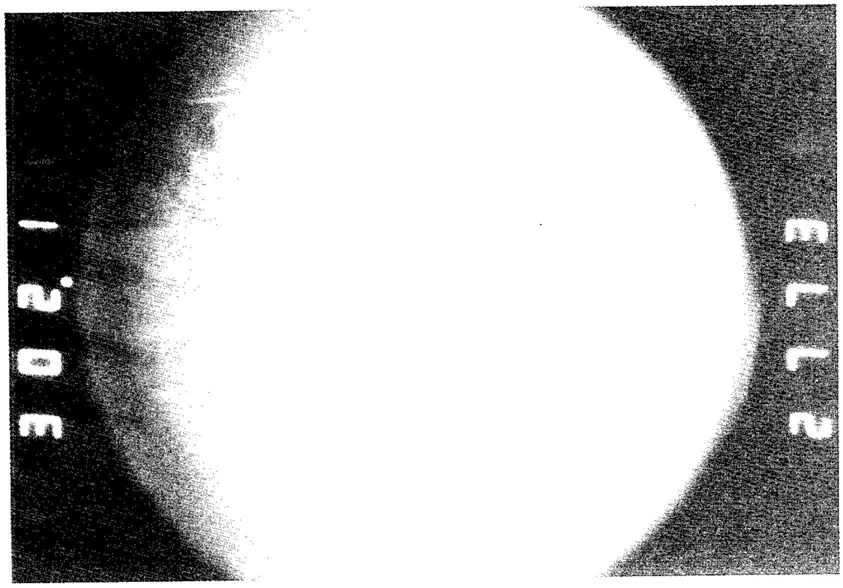

773-OD
Figure C. (60 ps-532 nm) One-hour FA shows very faint hyperfluorescence from a few of the 9 lesions.

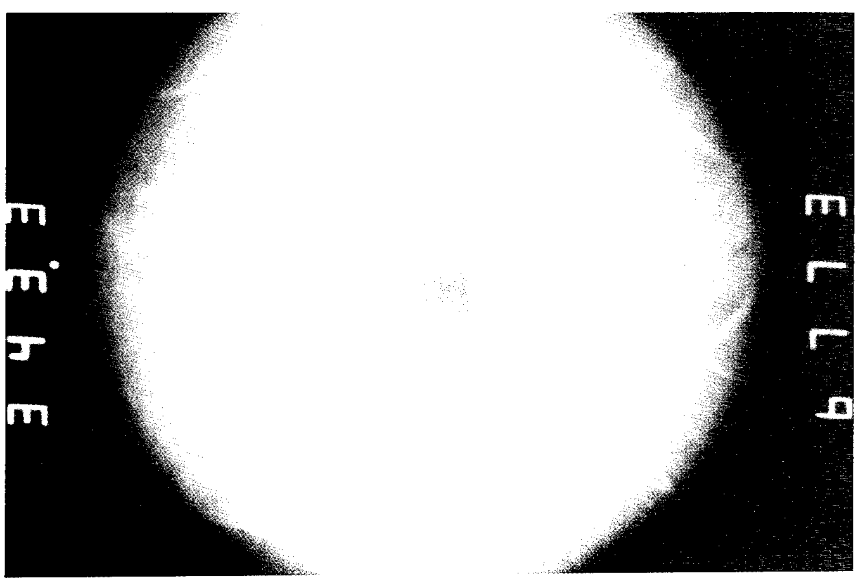

Figure D. The 24-hour FA demonstrates faint hyperfluorescence.

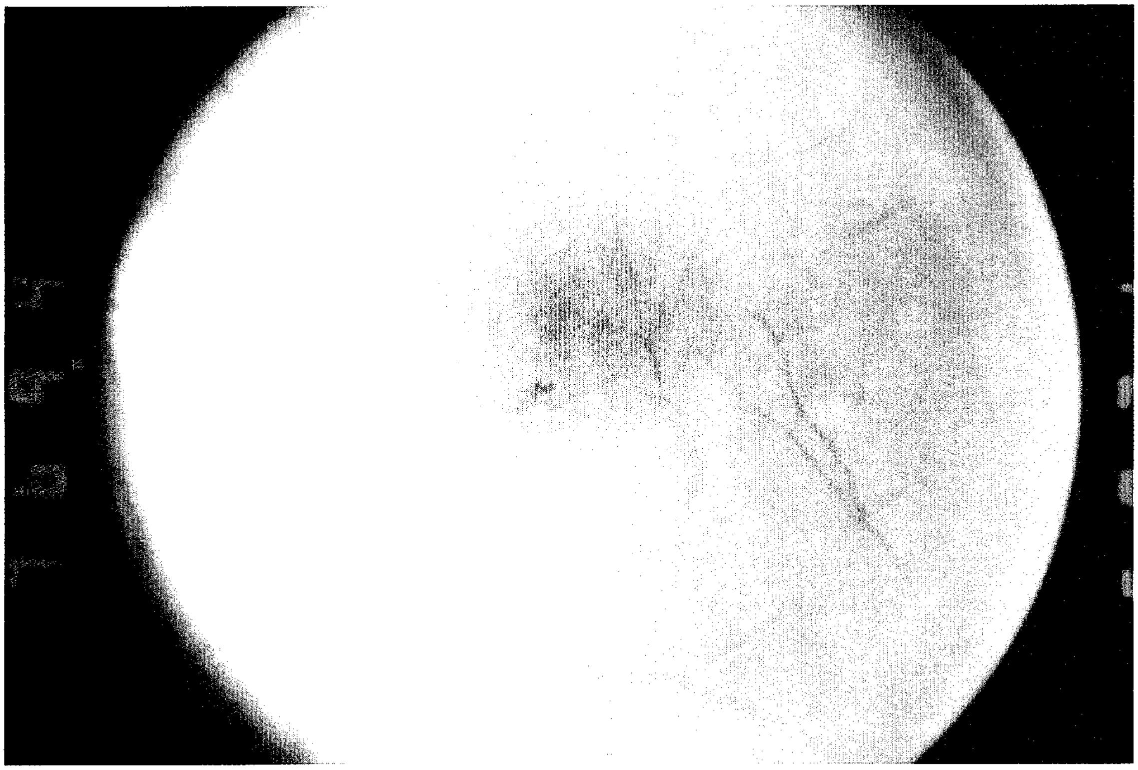

871-OS

Figure A. (60 ps-532 nm) 24-hour fundus photograph of 9 threshold lesions ranging in energy of delivery from 0.75 to 6.6 μJ. One hemorrhage occurred at 6.6 μJ and became apparent ophthalmoscopically within 10 minutes.

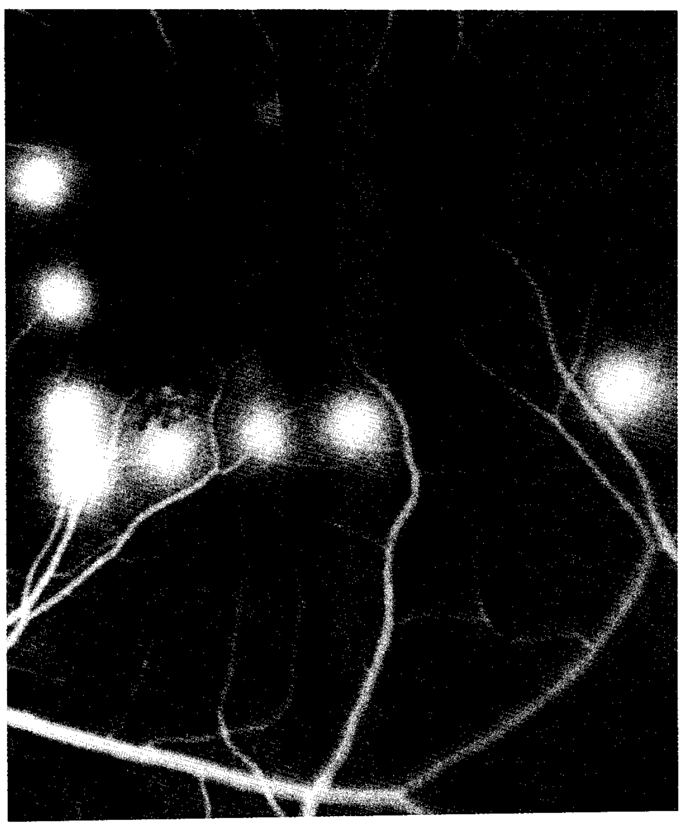

Figure B. The FA at 24 hours shows hyperfluorescence from MVLs.

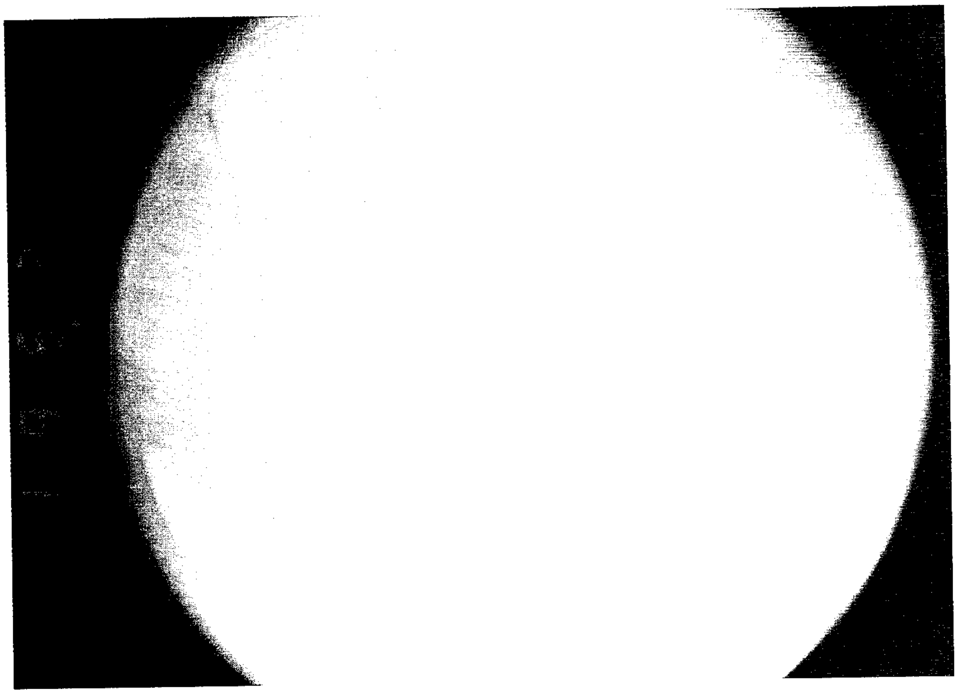

866-OD
Figure A. (4 ns-532 nm) One-hour fundus photograph of 25 threshold lesions ranging in energy from 0.14 to 5 μJ incident at the cornea (demonstrated on the corresponding fundus map). A number of very faint MVLs became ophthalmoscopically visible within 1 hour.

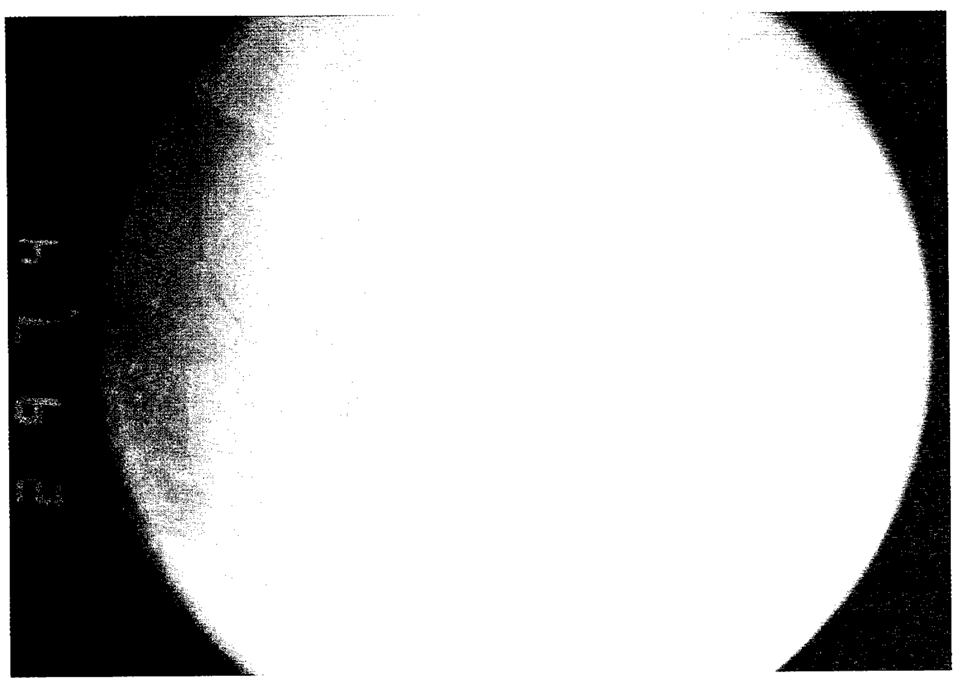

Figure B. The 24-hour fundus photograph shows an increase in the number of MVLs, and an increase in MVL lesion whiteness and diameter compared with the one-hour determination.

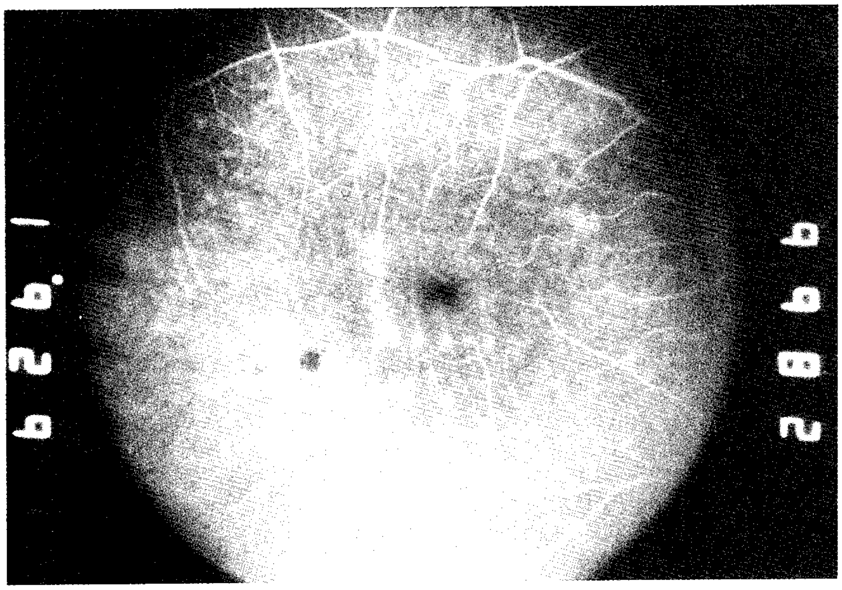

866-OD
Figure C. (4 ns-532 nm) One-hour FA, corresponding to Figure A, showing all lesions previously observed ophthalmoscopically.

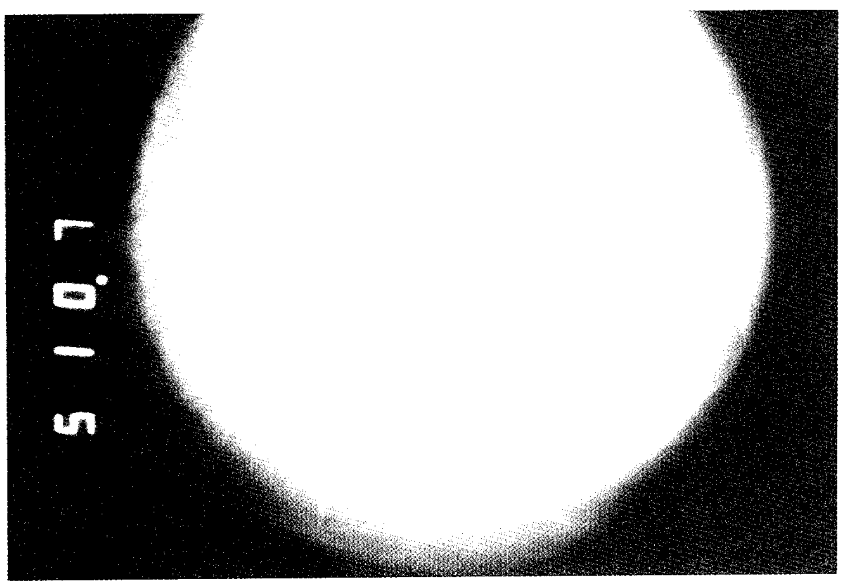

Figure D. 24-hour FA corresponding to Figure B. The MVLs emit faint hyperfluorescence and the angiograph demonstrates that fewer lesions were visible compared with 1 hour.
